Any ultrafast laser pulse is fully defined by its intensity and phase, either in time or frequency domain. Propagation in any media, inclusive of air, results in distortions of phase or amplitude. Large distortions in phase can be introduced by propagation of the beam even through optical elements with very low absorption such as lenses or prisms. This effect is frequently called temporal chirp and is due to chromatic (i.e. wavelength-dependent) dispersion.

Depending on their exact nature, phase distortions may broaden the pulse and modify its shape such that the pulse is not “transform- limited” anymore.

This means that the time-bandwidth relationship $\Delta t \Delta \nu \leq \kappa$ is not satisfied. Here κ depends on the shape of the spectrum ($\kappa = 0.441$ for a Gaussian pulse, $\kappa = 0.315$ for a hyperbolic secant pulse and $\kappa = 0.886$ for a square pulse).

1. Theory

Here for simplicity we will assume pulses with a temporal Gaussian shape. While this is only a convenient approximation it still gives a good idea of what is happening.

The electric field is defined by the expression

$$E(t) = E_0 e^{-i\omega_0 t} e^{-(1+ia)\left(\frac{t}{\tau_G}\right)^2}$$

With $\omega_0 = \frac{2\pi c}{\lambda_0}$, where λ_0 is the center wavelength (in our case 800 nm).

a is defined as the chirp parameter of the pulse and we will start without chirp so that $a=0$.

With τ_G defined as $\tau_p = \sqrt{2\ln(2)}\tau_G$, τ_p being the FWHM pulse duration.

The expression for the pulse then becomes

$$E(t) = E_0 e^{i\left(-\omega_0 t - \left(\frac{t}{\tau_G}\right)^2\right)}$$

A wave equation can be derived for the electric field E from the Maxwell equations (in absence of external charges and currents, and considering only non-magnetic permeability and uniform medium).

In Cartesian coordinates the equation is

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}\right) E(x, y, z, t) = \mu_0 \frac{\partial}{\partial t^2} P(x, y, z, t)$$

With μ_0 the magnetic permeability of free space

The Polarization P contains two terms, $P = P^L + P^{NL}$, i.e. the linear and non-linear term respectively. Assuming very weakly focused pulses (with no substantial changes in the x and y direction) we can neglect P^{NL} .

We then obtain the reduced wave equation

$$\left(\frac{\partial^2}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}\right) E(z, t) = \mu_0 \frac{\partial}{\partial t^2} P^L(z, t)$$

From classic electrodynamics we know that $P^L(z, t) = \epsilon_0 \chi(\omega) E(z, \omega)$

With χ the dielectric permissibility

By combining the two previous equations and moving into the frequency domain by Fourier transform we get:

$$\left(\frac{\partial^2}{\partial z^2} + \frac{\omega^2}{c^2} \frac{\partial^2}{\partial t^2} \epsilon(\omega)\right) E(z, \omega) = 0$$

With $\epsilon(\omega) = 1 + \chi(\omega)$ the dielectric constant We assume the susceptibility and dielectric constant here are real (i.e. there is no absorption).

A general solution for the previous equation is

$$E(\omega, z) = E(\omega, 0) e^{-ik(\omega)z}$$

Where the propagation constant k is determined by the linear optics dispersion relation

$$k^2(\omega) = \frac{\omega^2}{c^2} \epsilon(\omega) = \frac{\omega^2}{c^2} n^2(\omega)$$

n being the refractive index.

The main reason to work in the frequency domain is that phases are additive, unlike in the time domain.

2. Pulse Propagation Through Various Materials

Let's continue to assume a Gaussian pulse initially chirp-free (transform limited) with a 800 nm center wavelength. To calculate the pulse envelope we need to Fourier-transform the electric field into the frequency domain, add the frequency-dependent phase, Fourier-transform back in the time domain and calculate the norm of $E(t, z)$. To summarize, the propagated field in the frequency domain is given by

$$E(\omega, z) = E(\omega, 0) e^{-ik(\omega)z}$$

We then go back in the time domain in order to calculate the envelope and duration of the output pulse.

As a first step we need to determine the index of refraction of the different materials we will consider. Then we calculate the pulse duration after propagation through 5 mm and 10 mm of material starting with a

chirp-free 7 fs input pulse. This is representative of the typical pulse produced by the Coherent Vitara UBB Ti:Sapphire laser.

Typical spectral amplitude of pulse from Vitara UBB (Transform-limited pulse duration = 7 fs)

We are going to consider 6 media, including the most common types of glass used for laser optics, a very low dispersion material (CaF2), a high dispersion material (SF10) and finally air.

- Fused Silica
- Sapphire
- CaF2
- SF10
- BK7
- Air

Calculating the index of refraction

- Glass materials

For all glass materials, we use the well-known Sellmeier equation:

$$n^2(\lambda) = 1 + \frac{B_1\lambda^2}{\lambda^2 - C_1} + \frac{B_2\lambda^2}{\lambda^2 - C_2} + \frac{B_3\lambda^2}{\lambda^2 - C_3}$$

with λ in μm . The B and C coefficients are given in the table below.

Material	1 B1	2 B2	3 B3	4 C1	5 C2	6 C3
Fused Silica	0.6961663	0.4079426	0.8974794	0.00467914826	0.0135120631	97.9340025
Sapphire	1.43134930	0.650547130	5.34140210	0.00527992610	0.0142382647	325.017834
CaF2	0.5675888	0.4710914	3.8484723	0.00252642999	0.0100783328	1200.555973
SF10	1.62153902	0.256287842	1.64447552	0.0122241457	0.0595736775	147.468793
BK7	1.03961212	0.231792344	1.01046945	0.00600069867	0.0200179144	103.560653

Air (Edlen Model)

An accurate calculation of the refractive index of air requires a set of ten constants, in addition to its dependence on temperature, pressure and humidity

- Temperature
- Pressure
- Humidity

The ten constants for air are given in the table below.

K1	K2	K3	K4	K5
1.167052145280E+03	-7.242131670320E+03	-1.707384694010E+01	1.202082470250E+04	-3.232555032230E+06
K6	K7	K8	K9	K10
1.491510861350E+01	-4.823265736160E+03	4.051134054210E+05	-2.23855575678E-01	6.501753484448E+02

There are also five coefficients that depend on the temperature (expressed in K)

Ω_a	C_a	A_a	B_a	X_a
$\Omega_a = T + \frac{K_9}{T - K_{10}}$	$C_a = K_6\Omega_a^2 + K_7\Omega_a + K_8$	$A_a = \Omega_a^2 + K_1\Omega_a + K_2$	$B_a = K_3\Omega_a^2 + K_4\Omega_a + K_5$	$X_a = -B_a + \sqrt{B_a^2 - 4A_aC_a}$

We also need to include:

- Pressure vapor saturation :

$$P_{sv} = 10^6 \left(2 \frac{C_a}{X_a} \right)^4$$

- Partial vapor humidity :

$$P_v = \left(\frac{RH}{100} \right) P_{sv}$$

Where RH is the relative humidity and the pressure is expressed in Pascal (101325 Pa = 1 atm).

- Finally, there are seven additional constants :

A_b	B_b	C_b	D_b	E_b	F_b	G_b
8342.54	2406147	15998	96095.43	0.601	0.00972	0.003661

- We can then calculate the coefficient X_b

$$X_b = \frac{(1 + 10^{-8}(E_b - F_b(T - 273.15)))P}{1 + G_b(T - 273.15)}$$

Armed with these parameters, we calculate an expression for n_s

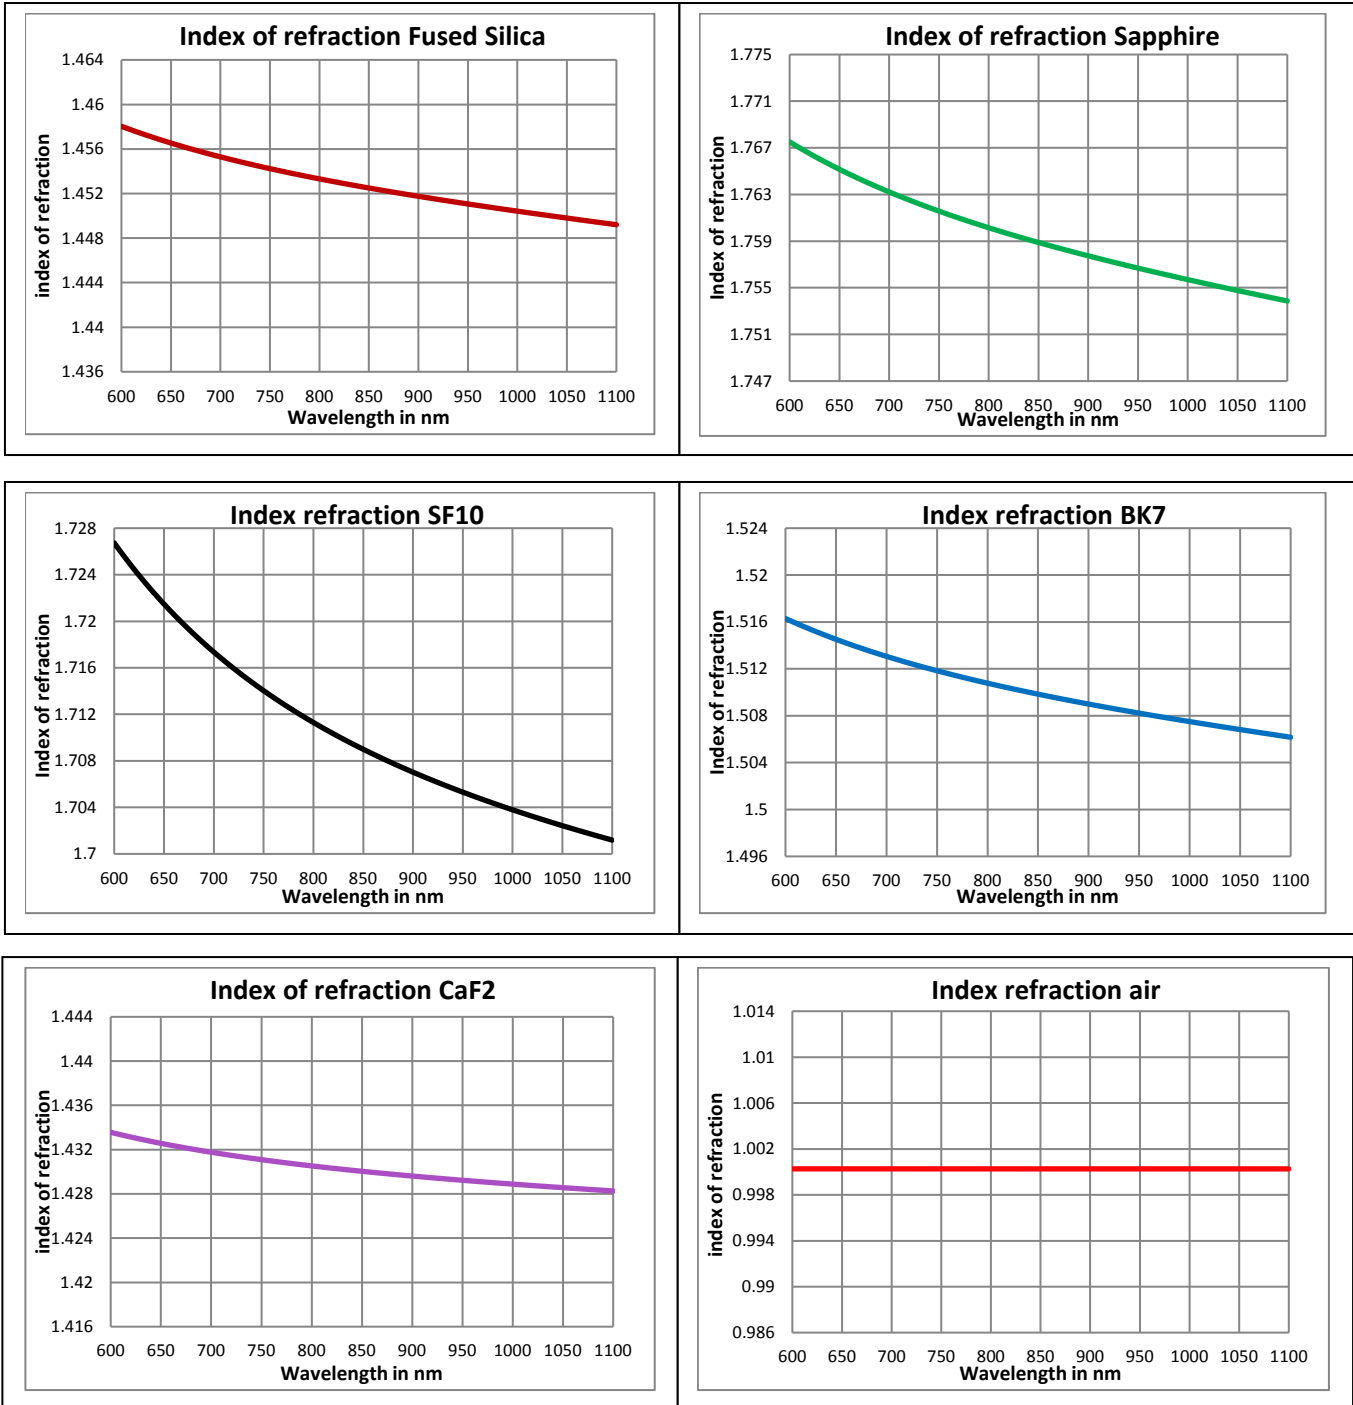

$$n_s(\lambda) = 1 + \left[\left(\frac{C_b}{38.9 - \frac{1}{\lambda^2}} \right) + A_b + \left(\frac{B_b}{130 - \frac{1}{\lambda^2}} \right) \right] 10^{-8}$$

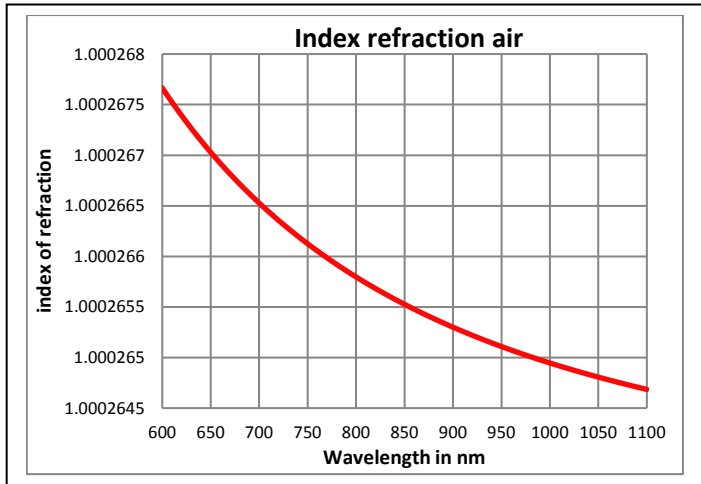

that we can use to calculate the full refractive index of air

$$n_{air}(\lambda) = 1 + P(n_s(\lambda) - 1) \frac{X_b}{D_b} - 10^{-10} \left(\frac{292.75}{T} \right) \left[3.7345 - \frac{0.0401}{\lambda^2} \right] P_v$$

Index of Refraction in the 600 nm to 1100 nm Range

By applying the previous formula for air and the different materials, we get the index of refraction curve from 600 nm to 1100 nm.

Refractive index of air on a much expanded scale shows its wavelength dependence for given temperature, pressure and humidity

The refractive indices of all materials are generally wavelength-dependent which means that each wavelength will propagate at a different speed resulting in pulse broadening of the output pulse.

The degree of broadening depends both on the change of the refractive index vs. wavelength and the initial bandwidth of the pulse.

Example: Broadening of a 7 fs Pulse through Different Materials

Depending on the material, pulse broadening can be minimal (in air) or dramatic (SF10) in as little as 5 mm of material. The k vectors (i.e. the combination of the three Cartesian components $n\omega/c$) are a good starting point to calculate how a pulse propagates through a

medium. Even if k (and n) doesn't change rapidly with the wavelength, this change will be much more visible in the derivatives.

Group Delay, Group Velocity and Group Velocity Dispersion

Let’s start with the Taylor expansion of the k vector to look at the different contributing factors:

$$k(\omega) = k_0 + \frac{\partial k}{\partial \omega} (\omega - \omega_0) + \frac{1}{2} \frac{\partial^2 k}{\partial \omega^2} (\omega - \omega_0)^2 + \frac{1}{6} \frac{\partial^3 k}{\partial \omega^3} (\omega - \omega_0)^3 + \frac{1}{24} \frac{\partial^4 k}{\partial \omega^4} (\omega - \omega_0)^4 + \dots$$

Group Velocity

The group velocity is defined as the velocity as which the pulse envelope travels

$$v_g = \frac{1}{\frac{dk}{d\omega}}$$

With $k = \frac{n(\omega)\omega}{c}$

This leads to:

$$v_g = \frac{c}{\left(n + \omega \frac{dn}{d\omega}\right)} = \frac{\frac{c}{n}}{1 + \frac{\omega}{n} \frac{dn}{d\omega}} = \frac{\left(\frac{c}{n}\right)}{\left(1 - \frac{\lambda}{n} \frac{dn}{d\lambda}\right)}$$

With $\lambda = \frac{2\pi c}{\omega}$

The first order derivative of k is therefore just a delay in time: the pulse propagates more slowly in a medium than in vacuum.

Group Velocity Dispersion

The Group Velocity Dispersion is defined as the second derivative of k with ω and is expressed in fs²/cm

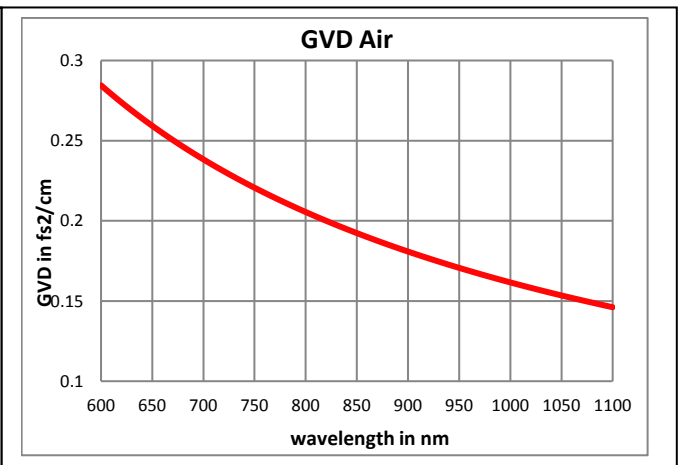

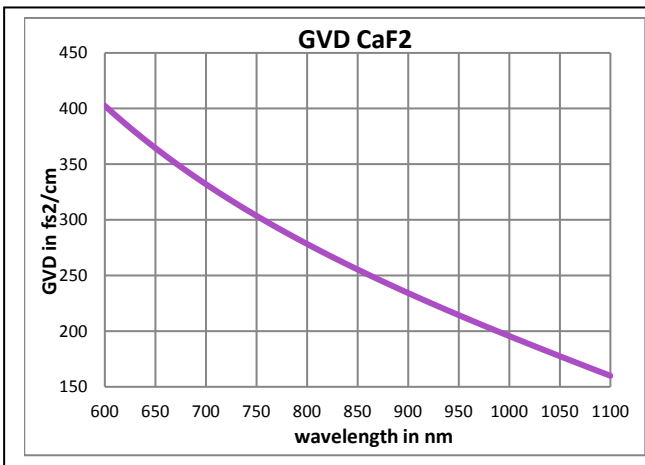

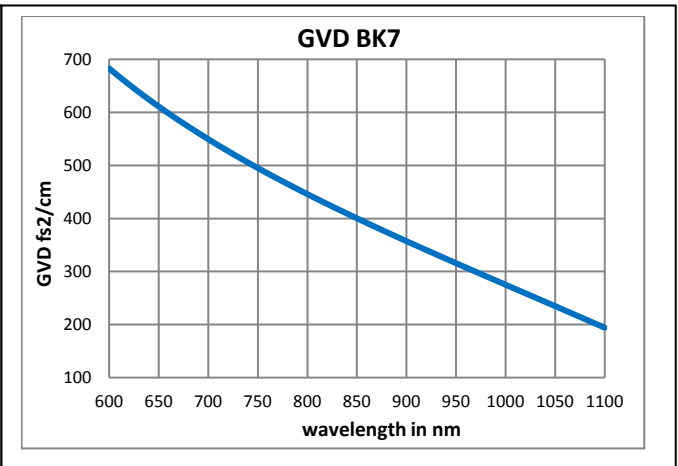

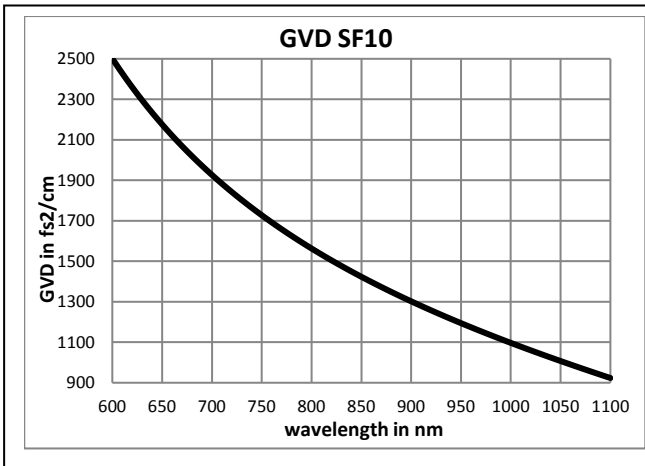

$$GVD = k''(\omega) = \frac{d}{d\omega} \left(\frac{1}{v_g} \right) = \frac{d^2 k}{d\omega^2} = \frac{\lambda^3}{2\pi c^2} \frac{d^2 n}{d\lambda^2}$$

The Group Delay Dispersion (GDD) is simply the product of the GVD and the propagation distance:

GDD= $k''(\omega)L$ (L amount of material in cm)

The GDD is expressed in fs².

Group Delay Dispersion for Various Materials:

Air has the lowest GVD: 0.21 fs²/ cm. After 1 meter of propagation in air the GDD at 800 nm is 21 fs²

Example: Output Pulse Duration as a Function of GDD:

The shorter the pulse the broader the bandwidth thus, the pulse broadening is due to dispersion.

Pulse Broadening and Distortion Due To TOD

To discuss the effects of higher order terms, let's now assume that we can fully compensate the GVD.

The Taylor expansion yields the formula:

$$k(\omega) = k_0 + \frac{\partial k}{\partial \omega}(\omega - \omega_0) + \frac{1}{2} \frac{\partial^2 k}{\partial \omega^2}(\omega - \omega_0)^2 + \frac{1}{6} \frac{\partial^3 k}{\partial \omega^3}(\omega - \omega_0)^3 + \frac{1}{24} \frac{\partial^4 k}{\partial \omega^4}(\omega - \omega_0)^4 + \dots$$

In order to determine the effects of high order dispersion first focus on the TOD by removing the first terms in the Taylor expansion

$$k(\omega_0) + \frac{\partial k}{\partial \omega}(\omega - \omega_0) + \frac{1}{2} \frac{\partial^2 k}{\partial \omega^2}(\omega - \omega_0)^2.$$

These terms represent respectively a constant, a fixed delay and the GVD.

We can then rewrite the k vector as:

$$k_{sub(\omega)} = k(\omega) - k(\omega_0) - \frac{\partial k}{\partial \omega}(\omega - \omega_0) + \frac{1}{2} \frac{\partial^2 k}{\partial \omega^2}(\omega - \omega_0)^2$$

And we finally end up with the following propagation equation:

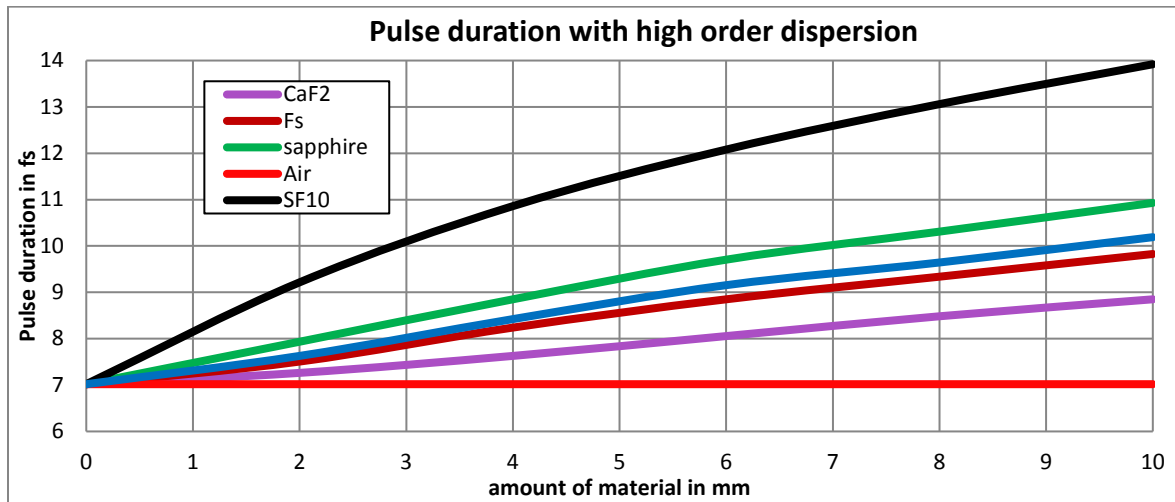

$$E(\omega, z) = E(\omega, 0)e^{-ik_{sub(\omega)}z}$$

The TOD is defined at the third derivative of the k vector:

$$TOD = \frac{d^3 k}{d\omega^3} = k'''(\omega) = -\left(\frac{\lambda}{2\pi c}\right)^2 \frac{1}{c} \left(3\lambda^2 \frac{d^2 n}{d\lambda^2} + \lambda^3 \frac{d^3 n}{d\lambda^3}\right)$$

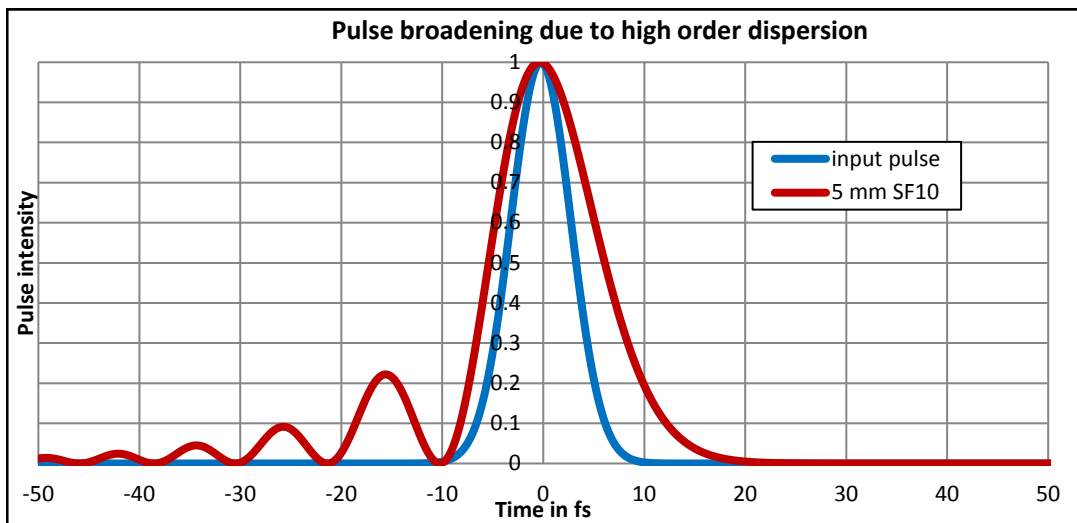

Example: Output Pulse Duration as a Function of TOD

The pulse broadening due to TOD for different materials is shown below.

The pulse broadening due to TOD is much lower than the GVD term (20 times) but the output pulse experiences some distortion as we can see after just 5 mm of SF10 knowing all the GDD has been perfectly compensated for here.

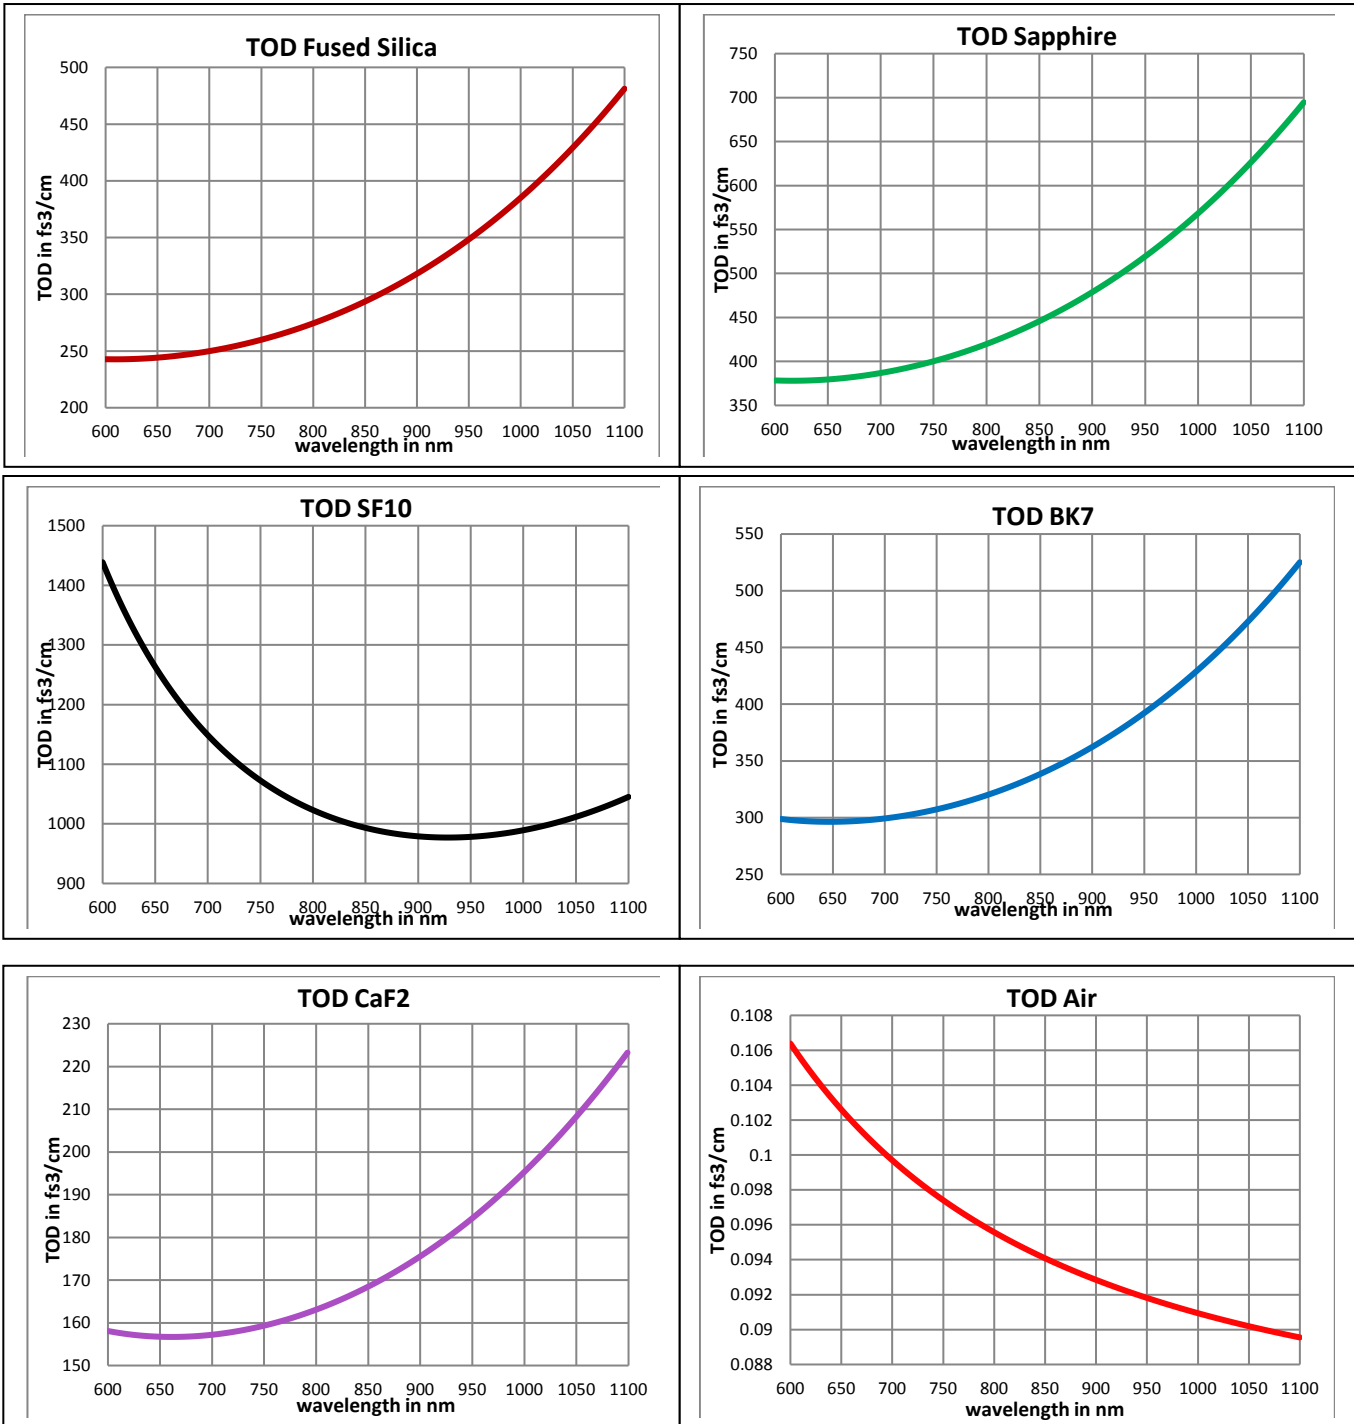

Example: Output Pulse Shape for SF10

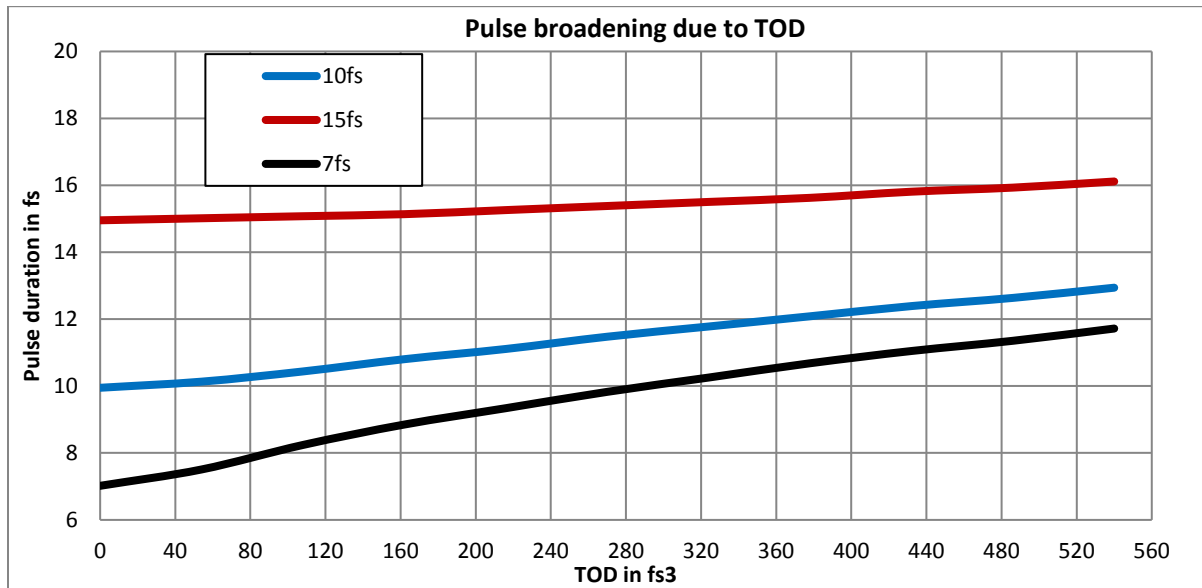

Even if the pulse broadening is not dramatic (we go here from 7 fs to 11 fs), the pulse shape degrades considerably as multiple side pulses may negatively affect some experiments.

TOD Dispersion Curve for Various Materials

TOD for Various Materials

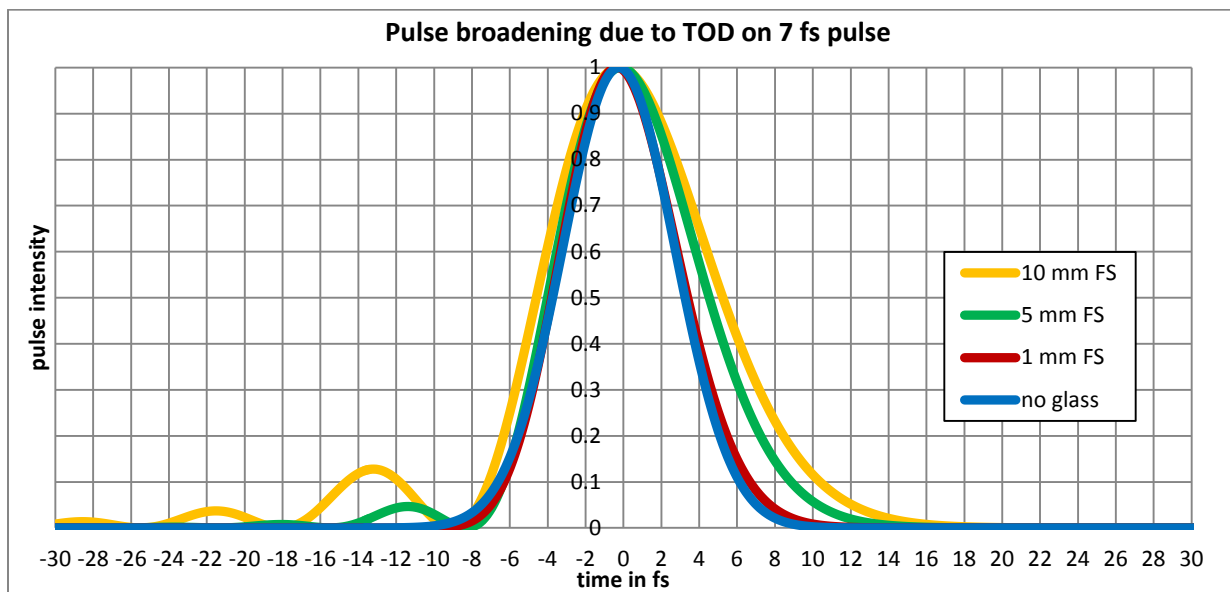

Output Pulse as a Function of TOD for Multiple Input Pulse Durations

Like in the case of GDD, longer pulses (with narrower bandwidth) are less sensitive to the third order dispersion term.

A Very Short Pulse Propagating Through Fused Silica Glass of Various Thicknesses
 the TOD of Fused Silica Is 274 Fs³/Cm

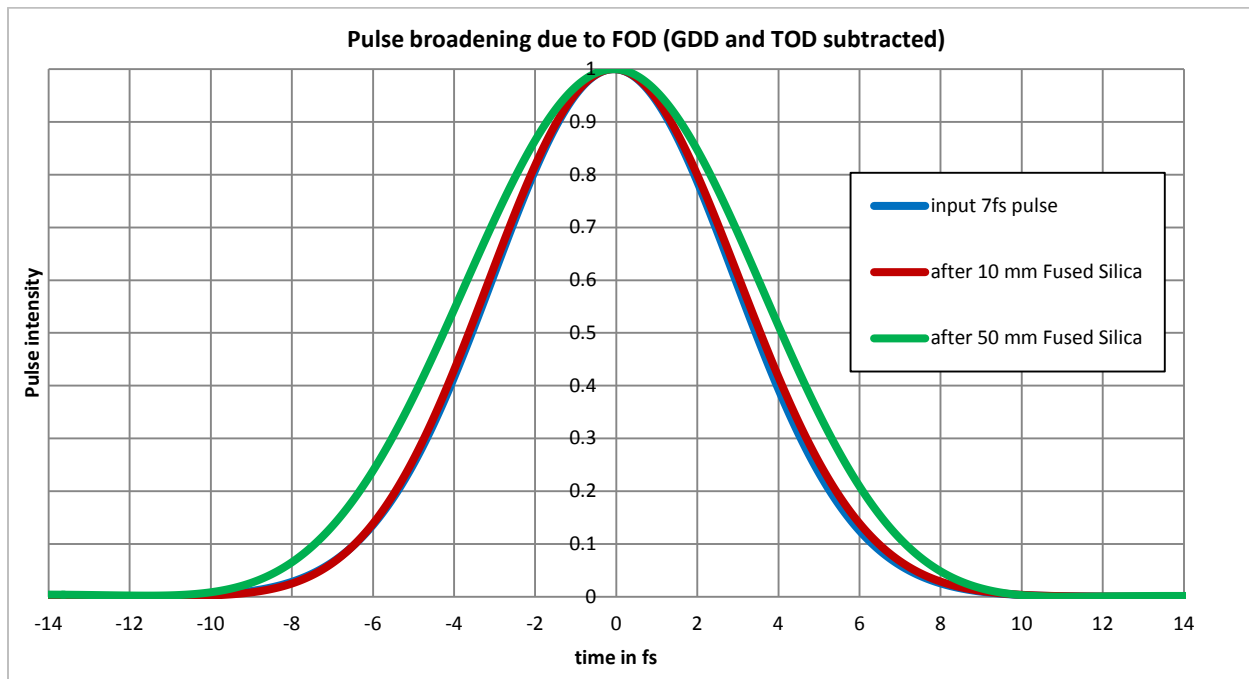

Fused Silica is the most commonly used glass material, together with BK7. Even if the pulse broadening is just a few femtoseconds (from 7 to 10 fs) the pulse shape becomes so distorted that compensation for TOD

becomes almost mandatory for many applications involving very short pulses. This can be accomplished by introducing so-called Negative Dispersion Mirrors (NDM) designed for TOD (and GVD) compensation.

Pulse Broadening and Distortion Due FOD and Higher Order Dispersion

Let's now assume perfect compensation for GDD and TOD: this means that the fourth order is the next most significant residual contribution. As shown in the

simulation below, after 10 mm propagation in Fused Silica the pulse broadens to 7.3 fs. Also, after a 50 mm of Fused Silica, the output pulse duration becomes 8 fs with very low distortion in the pulse shape. This means that even for a 7 fs pulse, we don't really need to compensate for FOD and higher order dispersion.

Summary of Pulse Broadening Effects in Various Materials

Ultra broad band lasers generating extremely short pulses (like Vitara UBB) are subject to strong pulse broadening because of the dispersive effects taking place during propagation in any material.

A simple 1 millimeter thick **fused silica plate will double the output pulse duration of the laser** (from 7 to 15 fs) and considering that a typical lens has a thickness of at least 3-4mm, GDD compensation is required in order to maintain the original pulse duration. Even propagation in one meter of air stretches the pulse to 10 fs.

Ideally one should use low dispersion glass like CaF_2 but this is not always readily available. Fused Silica and BK7 are acceptable choices but high GVD materials like SF10 have to be avoided. A good rule of

thumb is to stay away from materials with a GVD of more than $500\text{fs}^2/\text{cm}$.

GVD can be compensated by a prism pair or negative dispersion mirrors but this is not enough for such ultrashort pulses as they will still suffer great distortions (side pulses and ripples) due to higher order dispersion like TOD. TOD can be compensated by using appropriate combination of prism materials and separation in a prism compressor. This may take quite some space on an optical set-up and it may be hard not to optically clip the beam with some optics.

TOD can also be compensated by using NDMs with TOD compensation included in their coating design.

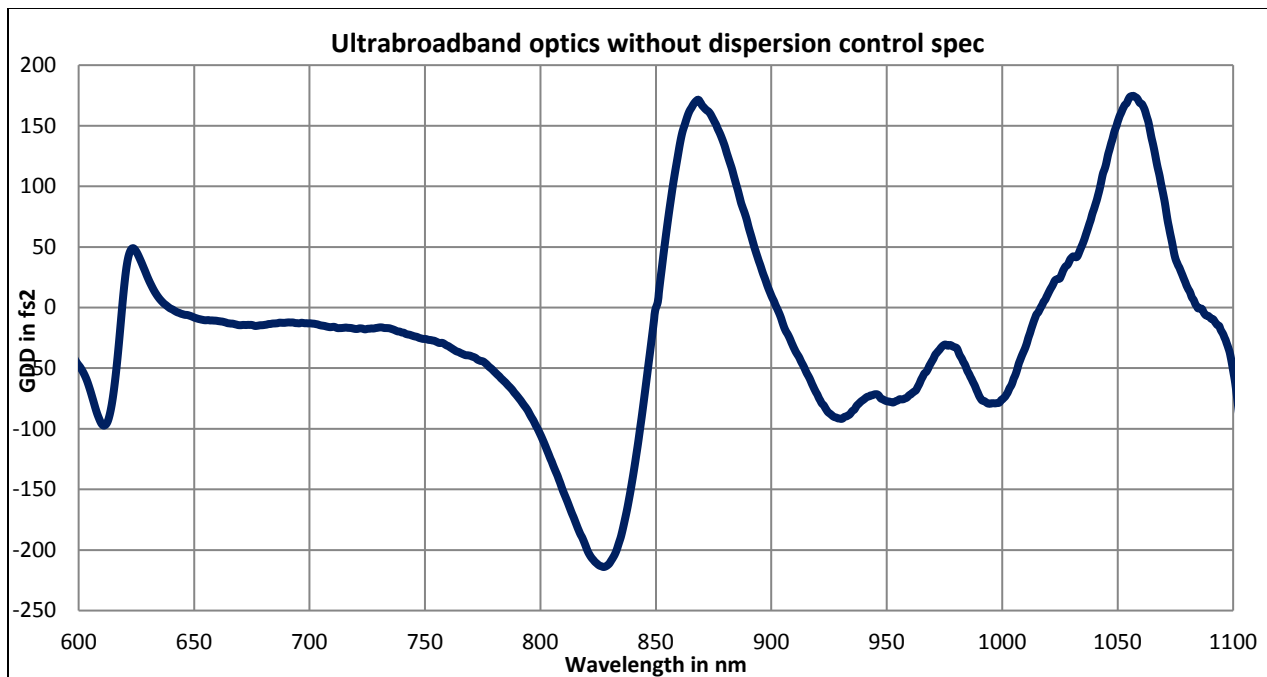

The main idea is still to limit the use of transmission optics as much as possible to reduce the quantity of material in the propagation path. Wherever possible, reflective optics should be used.

Choosing the proper optics

As mentioned earlier we have to limit, as much as possible, the amount of material introduced in the beam. In addition we need to make sure that any optic (reflective, transmissive or refractive) used is suited for

the laser bandwidth in terms of reflectivity and phase control.

Most of the “off-the-shelf” mirrors/ optics come with a reflectivity specification but without any specification on the dispersion. This means that the mirrors are not controlled for their GDD performance and one could unwittingly end up using an optic with a highly modulated GDD. An example of such an off-the-shelf mirror is shown below:

This optic displays a huge GDD jump at 820 nm and this would impart high order dispersion on the laser pulses, making very difficult to compress the pulses. Making sure that the mirrors are manufactured with controlled GDD is a better approach; however it may not be sufficient because many optics don't have a “hard” specification in terms of dispersion control.

A good rule of thumb for optical coatings is to assume that the dispersion control vanishes. (i.e. GDD becomes highly modulated) 20 nm to 30 nm

before the boundaries of the reflectivity specification (Although with some NDM designs it can be even worse).

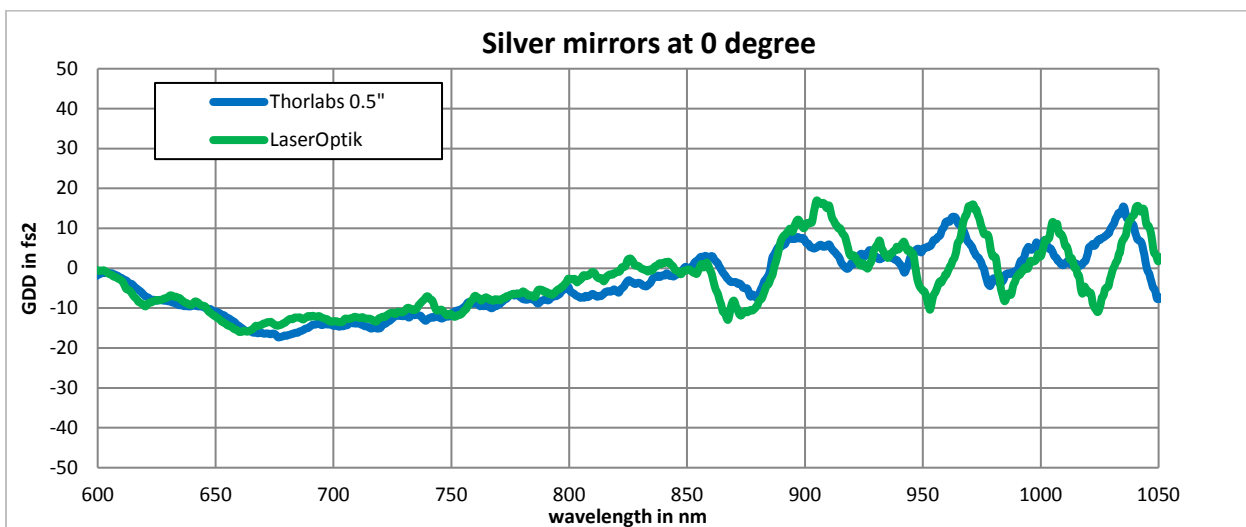

- Example: an optic with GDD optimization and reflectivity specified between 650 nm and 950 nm is likely to have GDD control only in the region 670 nm to 930 nm.

In summary, remember that lack of GDD control will lead to pulses that cannot be compressed easily, leading to overall system degradation.

Some Practical Tips

- Check the specification of all optics for proper Reflectivity and Phase (GDD) control
- A wavelength range 600 nm to 1000 nm is recommended
- Silver mirrors have a naturally flat phase at 600 nm to 1000 nm and work reasonably well. The down-side is the relatively high 3% loss per reflection
- For transmission or refractive optics it is better to use CaF2 or BaF2 rather than Fused Silica because these fluorides introduce less TOD (and GDD in case of CaF2)
- NDMs with TOD compensation can be purchased from these vendors (not a comprehensive list):
 - Layertec (some mirrors have TOD compensation)
 - Ultrafast Innovation
 - LaserOptik

Appendix A: Pulse Duration Measurement

In order to measure properly the pulse of broadband lasers like Vitara UBB (typically 7fs Transform limit for <10 fs laser and 6 fs Transform Limit for <8 fs option) we need to use the proper pulse measurement tool.

Many devices like FROGs, autocorrelators and SPIDERS are commercially available or home-built, however not all are suitable to match the repetition rate and pulse duration of these ultra-broadband oscillators.

At Coherent we typically use an FC spider manufactured by APE (Berlin, Germany). Details can

be found at <http://www.ape-america.com/> and <http://www.ape-berlin.de/>.

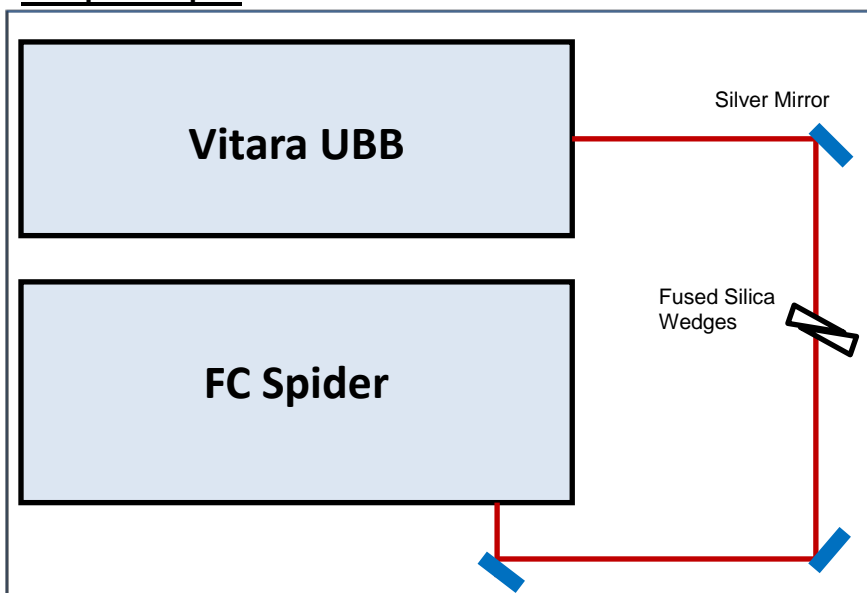

Our FC Spider has the following specifications:

Wavelength range	550 nm to 1050 nm
Spectral bandwidth	> 30 nm @ 800 nm
Pulse width range (for transform limited pulses)	5 - 30 fs
Max. pulse width (for non-transform limited pulses)	< 180 fs
Input polarization	linear / horizontal
Input power	> 100 mW @ 80 MHz, 10 fs
	~ 20 mW @ 1 kHz, 20 fs

This SPIDER properly matches the Vitara UBB output (roughly 600 to 1000 nm spectrum) both in bandwidth and pulse duration ranges. Any other device that

satisfies these specification listed above should be able to measure the pulses from Vitara UBB.

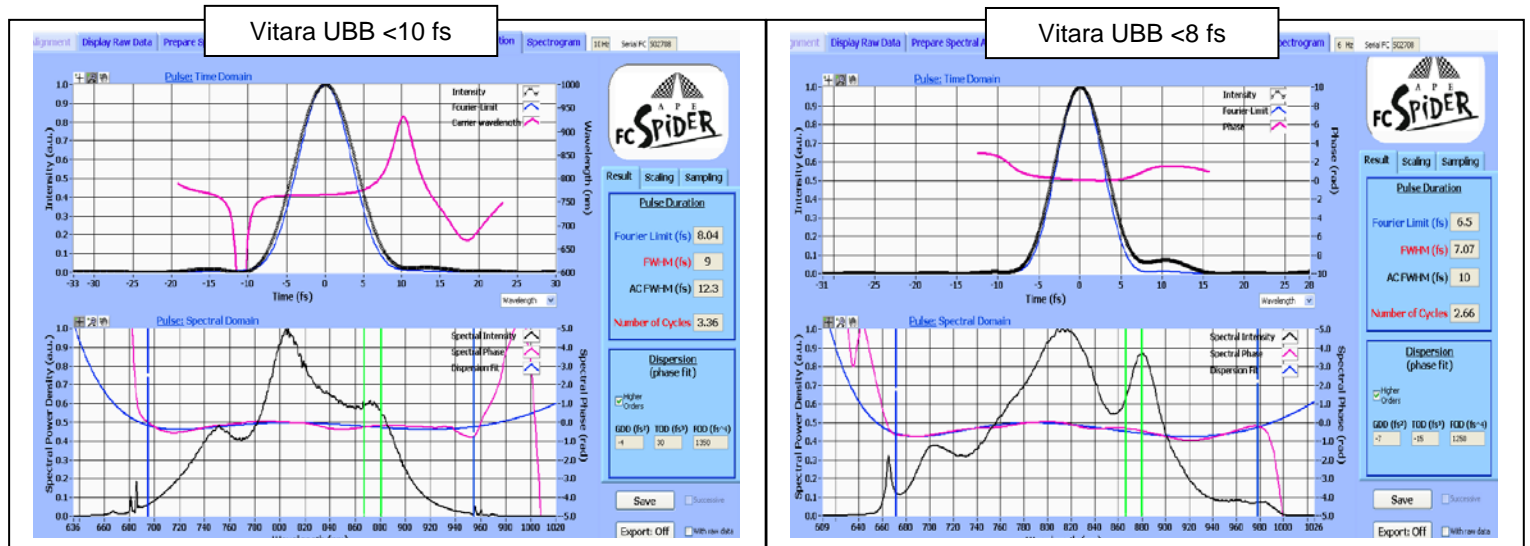

Setup Example:

- The Vitara output is intentional slightly negatively chirped and collimated
- All the routing mirrors used are silver coated
- A pair of thin Fused Silica wedges are used for fine tuning the dispersion

The Vitara output is deliberately slightly negatively chirped so that insertion of material like a thin pair of wedges results in optimally compressed pulses.

Typical Measurements
